Observational studies

A B S T R A C T

Objective: A systematic review of observational studies was performed to address the strength of evidence for an association between actual and perceived exposure to electromagnetic fields (EMF) and non-specific physical symptoms (NSPS) in the general population. To gain more insight into the magnitude of a possible association, meta-analyses were conducted.

Methods: Literature databases Medline, Embase, SciSearch, PsychInfo, Psyndex and Biosis and additional bibliographic sources such as reference sections of key publications were searched for the detection of studies published between January 2000 and April 2011.

Results: Twenty-two studies met our inclusion criteria. Qualitative assessment of the epidemiological evidence showed either no association between symptoms and higher EMF exposure or contradictory results. To strengthen our conclusions, random effects meta-analyses were performed, which produced the following results for the association with actual EMF: for symptom severity: Headache odds ratio (OR) = 1.65; 95% confidence interval (CI) = 0.88–3.08, concentration problems OR = 1.28; 95% CI = 0.56–2.94, fatigue-related problems OR = 1.15; 95% CI = 0.59–2.27, dizziness-related problems OR = 1.38; 95% CI = 0.92–2.07. For symptom frequency: headache OR = 1.01; 95% CI = 0.66–1.53, fatigue OR = 1.12; 95% CI = 0.60–2.07 and sleep problems OR = 1.18; 95% CI = 0.80–1.74. Associations between perceived exposure and NSPS were more consistently observed but a meta-analysis was not performed due to considerable heterogeneity between the studies.

Conclusions: This systematic review and meta-analysis finds no evidence for a direct association between frequency and severity of NSPS and higher levels of EMF exposure. An association with perceived exposure seems to exist, but evidence is still limited because of differences in conceptualization and assessment methods.

1. Introduction

Ongoing environmental exposures related to technological development such as air pollution, toxic substances and radiation give rise to people’s worries about possible impact on health (Petrie et al., 2001). A part of the general population has concerns about potentially harmful effects from electromagnetic fields (EMF) emitted either by sources of near-field exposure such as mobile phones or from far-field exposure sources such as base stations for mobile telecommunication and high-voltage overhead powerlines (Blettner et al., 2009; Hutter et al., 2004; Schreier et al., 2006); in the latter case, exposure is often continuous and people perceive it as less controllable (Schreier et al., 2006). Not only concerns about increased risk for long-term conditions such as cancer are reported, but also a variety of symptoms without a clear pathological basis is attributed to relatively low-level exposure to EMF, such as redness, tingling and burning sensations (in the facial area), fatigue, tiredness, lack of concentration, dizziness, nausea, heart palpitation and digestive disturbances (Mild et al., 2006; WHO, 2005). The estimated prevalence of these non-specific physical symptoms (NSPS) ranges between 3.5% and 10% (Blettner et al., 2009; Schreier et al., 2006; Schrottner and Leitgeb, 2008).

Although evidence that could support a causal association between exposure and outcome seems to be insufficient and inconsistent (Röösli and Hug, 2011; Röösli et al., 2010; Rubin et al., 2009), a possible effect of higher exposure levels cannot be ruled out yet because of methodological obstacles, primarily regarding bias related to exposure assessment and study design (Röösli, 2008; Röösli et al., 2010). Systematic reviews focusing mainly on experimental evidence suggest rather a nocebo effect which could imply an underlying

Abbreviations: CI, confidence interval; EMF, electromagnetic fields; NSPS, non-specific physical symptoms; OR, odds ratio.

psychological mechanism that leads to physiological responses and subsequent symptoms (Rubin et al., 2009). Therefore, perceived/self-reported exposure, even poorly correlated with actual exposure levels (Inyang et al., 2008; Vrijheid et al., 2009) could be an important factor to investigate, since it is associated with NSPS (Balatsas et al., 2011) and might have a distinct role in symptom report via concerns about possible health effects caused by EMF (Röösli, 2008).

Despite the fact that the vast majority of EMF research focuses on possible associations with chronic medical conditions such as leukemia and glioma, during the last years the international scientific literature on EMF and NSPS has grown, both with respect to objectively measured and self-reported exposure. In order to elucidate the pathways that lead to the report of EMF-related NSPS it is necessary to systematically examine these two aspects of exposure. Observational studies are highly important due to the investigation of long-term exposure and effects in large population samples. Taking into consideration the methodological obstacles that epidemiological research on EMF and health is confronted with, important conclusions can be drawn from comprehensive reviews and meta-analyses rather than from a single study, as has been recently highlighted by Rothman (2009).

No systematic review has been conducted yet concentrating exclusively on observational studies on various sources of general population exposure to EMF and NSPS, assessing the existing evidence in terms of both actual and perceived exposure. In addition, no meta-analysis has been performed in the past on epidemiological data on EMF and NSPS.

The present paper attempts to identify the relevant observational epidemiological studies conducted in the last eleven years (2000–2011), in order to systematically assess the strength of evidence for an association between objectively measured (actual) and self-reported (perceived) exposure to EMF and NSPS.

2. Methods

2.1. Data sources and searches

The following electronic databases were searched to detect relevant studies that were published between January 2000 and April 2011: Medline (US National Library of Medicine, Bethesda, Maryland), Embase (Elsevier B.V., Amsterdam, The Netherlands), SciSearch (Institute for Scientific Information, The Thomson Corporation, Stamford, Connecticut), PsychInfo (American Psychological Association, Washington, DC), Psynex (German Institute of Medical Documentation and Information, Cologne, Germany) and Biosis (The Thomson Corporation, Stamford, Connecticut). There was no language restriction.

A wide range of keywords was used, related to EMF exposure and symptoms, which is presented in Table 1. In addition to the electronic database searches, the reference sections of previous systematic reviews, key papers, international reports on EMF and health and research databases of websites focused on the issue of EMF such as the “EMF Portal” and the WHO webpage were checked for potentially relevant articles.

2.2. Inclusion criteria

For paper selection, four criteria were used:

I. An exposure criterion. Only studies examining symptom report in relation to general population exposure to radio-frequency (RF) EMF which did not exceed the levels established by the International Commission of Non-ionizing Radiation (ICNIRP) (1998) were considered as eligible for the review, covering a wide range of frequencies such as GSM, UMTS, FM radio, TDAB, WIMAX/LTE, analog TV and DVB-T, TETRA, DECT and WLAN/WIFI. The exposure could be either actual/objectively measured when an indicator of actual exposure levels was assessed (e.g. field strength), or perceived/self-reported when it was assessed by self-reported instruments. Studies on occupational exposure are not covered in this review.

II. A symptom report criterion. Studies should examine a range of self-reported physical/somatic symptoms without a diagnosed pathological or psychopathological cause. Since this review focuses on somatic symptoms as an outcome, results regarding mental health outcomes (e.g. depression) that are possibly presented by some of the reviewed studies are not included. Studies focusing on a possible association between EMF and chronic medical conditions (e.g. cancer) were also excluded. Moreover, studies focusing exclusively on ergonomic problems (such as musculoskeletal symptoms related to posture of computer users) are not covered in this paper.

III. A population criterion. The eligible studies recruited samples of healthy individuals being at least 12 years old. Studies focusing only on individuals with self-reported idiopathic environmental intolerance attributed to EMF (IEI-EMF) were not included.

IV. A study criterion. Only primary observational studies (not reanalyses, conference presentations or reviews) from the peer-reviewed literature, investigating a potential exposure–response relationship (and not being restricted to descriptive analyses) were considered as suitable for inclusion. The term “observational” refers to non-experimental studies such as cross-sectional, case control and cohort studies, in which the possible association between EMF and NSPS was investigated without an attempt to affect the exposure or the outcome. In the case of so-called “natural experiments” which combine both experimental and observational design, only the baseline results were included (if given). Case (individual) studies were excluded.

2.3. Evaluation of the quality of information

The adequacy of the information provided in the articles was assessed based on the “Strengthening the Reporting of Observational Studies in Epidemiology (STROBE)” statement (Vol Elm et al., 2007). Minimal quality criteria were:

a) Provision of adequate information regarding study design, sample size, recruitment and characteristics.

b) Clear description of the methods that were followed for the assessment of the exposure and outcome.

c) Provision of adequate information regarding the performed statistical analyses including confounding adjustment (which should be at least for age and gender).

In case a selected article did not meet the forenamed basic criteria, further information was requested from the original authors. If there was no response, the article was excluded.

2.4. Procedure

For each included study, the following data were abstracted: references, study design, respondents’ characteristics (including selection, sample size, response rate, age range or mean, gender distribution and country), exposure source and intensity recalculated in volts per meter (V/m), exposure assessment, outcome assessment, variables included as potential confounders and statistically significant associations between exposure and outcomes (Tables 2 and 3).

The literature search, evaluation of inclusion and exclusion criteria and evaluation of the quality of information in the articles were conducted by the first two authors, with uncertainties resolved through consultation with the rest of the co-authors.

More specifically, in the first stage the titles and abstracts that were derived from the search process were independently screened, to evaluate whether they met the exposure and symptom criteria. The abstracts or titles were examined. Next, the hard copies of the publications fulfilling the inclusion criteria were assessed in terms of the population and study criteria. Finally, an article quality evaluation was performed.

2.5. Data synthesis and analysis

After paper selection and data extraction, the included studies were screened for meta-analysis suitability. Studies were considered eligible if they assessed the same symptoms, or outcomes of similar meaning (e.g., fatigue and exhaustion), employed comparable methods to assess exposure and used comparable instruments and cut-off points to assess the outcome(s). Based on these parameters, it was decided to conduct meta-analyses on the effect of objectively measured electromagnetic field strength on different NSPS. The risk of bias due to exposure misclassification, selective participation and confounding was assessed for the relevant studies (Table 4), as proposed by Grimes and Schulz (2002). Studies with a high risk of one or more of the basic categories of bias were not included in the meta-analyses; the method of rating was broadly based on schemes used by previous systematic reviews (Röösli et al., 2010). Finally, studies were included only if the adjusted odds ratios (OR) (risk for reference exposure category versus risk for highest exposed category) and 95% confidence interval (95% CI) for the association were given or derivable.

Studies were grouped on the basis of the investigated symptoms and assessment (frequency/chronicity or severity/acuteness). For each reported outcome the log-transformed OR value and standard error were calculated. Effect sizes were weighted using the inverse of each reported outcome the log-transformed OR value and standard error. For each included study, the following data were abstracted: references, study design, respondents’ characteristics (including selection, sample size, response rate, age range or mean, gender distribution and country), exposure source and intensity recalculated in volts per meter (V/m), exposure assessment, outcome assessment, variables included as potential confounders and statistically significant associations between exposure and outcomes (Tables 2 and 3).

The literature search, evaluation of inclusion and exclusion criteria and evaluation of the quality of information in the articles were conducted by the first two authors, with uncertainties resolved through consultation with the rest of the co-authors.

More specifically, in the first stage the titles and abstracts that were derived from the search process were independently screened, to evaluate whether they met the exposure and symptom criteria. The abstracts or titles were examined. Next, the hard copies of the publications fulfilling the inclusion criteria were assessed in terms of the population and study criteria. Finally, an article quality evaluation was performed.

2.6. Definitions

In the present paper, three main terms are consistently used to describe the exposure and outcome: Actual EMF Exposure, Perceived EMF Exposure and Non-specific Physical Symptoms (NSPS).

Actual Exposure refers to EMF levels assessed by objective exposure indicators/proxies such as measurements of field strength. Perceived Exposure is determined as the subjective estimation of the magnitude of being exposed to EMF (sources), assessed by self-reported instruments. In this review, perceived exposure is investigated as an indicator of a nocebo effect and not as a proxy for actual exposure. NSPS refers to the health outcomes, as a general and neutral term which does not imply any causal link with a particular pathogenic source.

3. Results

3.1. Study characteristics

The database investigation yielded 640 abstracts in total: 400 from Medline and 240 from the other 5 electronic databases. The citations that were derived from Medline were complete including both title and abstract, while only the title was available for a considerable amount of citations in the other databases.

Whenever necessary, we sought for further information by requesting the full articles. Overall, 608 studies were excluded, because they did not meet the inclusion criteria (Fig. 1). A further search in additional bibliographic sources yielded 9 studies, which all appeared to be eligible. Forty-one articles were found to be eligible for the review; evaluation with regards to article quality of reporting led to a further exclusion of 21 studies (Appendix A). Finally, 20 research articles from the peer-reviewed literature were accepted for this review, representing 22 studies (Tables 2 and 3); eighteen of cross-sectional design, three longitudinal and one case–control study.

Ten studies investigated NSPS in relation to actual exposure, 9 studies on perceived exposure and 3 studied both aspects. Response rates were given in 17 studies, ranging from 37% to 88% for the studies on actual exposure and from 363 to 75% for the studies on perceived exposure. Sample sizes ranged between 54–420 095 (actual exposure studies) and 132–4520 subjects (perceived exposure studies). The percentage of female participants ranged between 15%–66% and 10%–66% respectively.

In most of the studies on actual exposure, mobile phone base stations constituted the EMF source of primary concern in the investigation (n = 8), while most of the studies providing data on the effect of perceived exposure on NSPS, focused on mobile/wireless phone use (n = 9). The majority of the studies was conducted in Europe (n = 20).

3.2. Actual exposure and NSPS

Thirteen studies in total provided data on the association between actual exposure and NSPS; eleven of cross-sectional design, one longitudinal study and one registry-based cohort (Table 2). Exposure (24 h) assessment was based on field strength spot measurements (n = 7 studies), use of personal dosimeters during waking hours (n = 4), exposure prediction modeling (n = 1) and geo-coded distance to base stations (n = 1). The time weighted average electric field strength in these studies could be approximately estimated as ≤0.1 V/m for the reference (low/unexposed) group of participants and did not exceed the 5 V/m for the individuals being considered as highly exposed.

Eight studies used standardized instruments to assess NSPS (Altpeter et al., 2006; Berg-Beckhoff et al., 2009; Blettner et al., 2009; Heinrich et al., 2010; Heinrich et al., 2011; Hutter et al., 2006; Mohler et al., 2010; Thomas et al., 2008). The "Von Zerssen complaint list" (Von Zerssen, 1976) was the most consistently used symptom scale. Overall, the most frequently investigated outcomes were headache, sleep problems, dizziness-related symptoms (such as vertigo), fatigue-related symptoms (such as exhaustion) and concentration problems. The majority of the studies did not show a significant effect of exposure on fatigue related-symptoms (n = 4 versus n = 1) and concentration difficulties (n = 3 versus n = 1).

Findings for headache were contradictory, since n = 4 studies reported a significant association with higher exposure levels, while n = 3 suggested no association. Results for sleep problems and dizziness-related symptoms were also found to be contradictory (n = 4 versus n = 5 and n = 3 versus n = 3 respectively). Two studies used symptom total scores as outcome (Berg-Beckhoff et al., 2009; Blettner et al., 2009); one did not find any exposure effect while the other showed a weak association, although only geo-coded distance to base stations was employed (Blettner et al., 2009), which is a not a sufficient proxy for actual exposure (Frei et al., 2010).

Evidence regarding other NSPS (e.g. migraine and memory problems) was limited and inconsistent. Studies employing more advanced exposure characterization methods such as personal dosimeters and exposure prediction modeling were less likely to find significant associations (Heinrich et al., 2010, 2011; Mohler et al., 2010; Thomas et al., 2008). Apart from age, gender and socio-economic status, the most examined potential confounders were perceived mobile phone use, urbanization level,

* Analyses yielded similar associations for NMT use.
* The studies of Milde-Busch et al. (2010), Heinrich et al. (2010, 2011) were based on the same sample.
* Results from participants under the age of 12 years were excluded.
smoking habits and risk perception/concerns related to possible health effects caused by EMF exposure.

It should be mentioned that although the studies of Heinrich et al. (2010, 2011) and Milde-Busch et al. (2010) investigate different outcomes (e.g. acute versus chronic symptoms), they are based on the same sample.

3.3. Perceived exposure and NSPS

Twelve studies provided data on the association between perceived exposure and NSPS; ten of cross-sectional design, one case–control study and one cohort (Table 3). Perceived exposure was measured based mainly on the daily mobile phone use.

![Flow diagram outlining the study selection process.](image)
Seven studies used standardized instruments to assess symptoms (Heinrich et al., 2010, 2011; Herr et al., 2005; Hutter et al., 2010; Miïle-Busch et al., 2010; Mohler et al., 2010; Thomeé et al., 2011). The most consistently examined outcomes were headache, dizziness, sleep problems, concentration disturbances, burning sensations in the facial area, ears or body and tinnitus. Most of the studies showed an effect of perceived exposure on concentration problems (n=4 versus n=2) and headache (n=5 versus n=3), while no statistically significant effect was demonstrated for the majority of the studies on sleep problems (n=4 versus n=1) and dizziness (n versus n=2).

Results were contradictory for fatigue-related symptoms (n=4 studies reported significant associations versus n=3 that did not report significant results), tinnitus (n=2 versus n=1) and burning sensations (n=2 versus n=2). Again, evidence regarding other NSPS was limited and inconsistent. Apart from age, gender and socio-economic status, there was a quite consistent adjustment for video display terminal (VDT) use, stress-related variables and urbanization level as potential confounders. Overall, 5 studies were excluded from the meta-analyses (Abdel-Rassoul et al., 2006; Abelín et al., 2006; Altpeter et al., 2006; Blettner et al., 2009; Preece et al., 2007), primarily due to high risk for bias and lack of comparability. One study was excluded because it was not possible to obtain the OR and 95% CI (Berg-Beckhoff et al., 2009).

Finally, depending on the outcome, 2 to 4 studies of cross-sectional design were included in the meta-analyses (Heinrich et al., 2010, 2011; Hutter et al., 2006; Mohler et al., 2010; Thomas et al., 2008) (Table 5). Most of the studies characterized exposure levels using personal dosimeters (Heinrich et al., 2010, 2011; Thomas et al., 2008). The investigated NSPS were headache, concentration problems, fatigue-related problems, dizziness-related problems and sleep problems. Since studies used self-reported scales to measure either the frequency of symptoms (labeled as “chronic”) or severity (labeled as “acute”), apart from the classification of the studies on the basis of the investigated symptom, they were also grouped based on these types of measures in order to enhance their comparability. All the “acute” NSPS were measured with items from the “Von Zerssen complaint list” (Von Zerssen, 1976). Among the 3 studies assessing these symptoms (Heinrich et al., 2010; Hutter et al., 2006; Thomas et al., 2008), two used the same cut-off points (Heinrich et al., 2010; Hutter et al., 2006); a symptom was considered to be present if it was “at least of weak intensity”, which in the study of Thomas et al. (2008) if it was “at least moderate”. Regarding the “chronic” NSPS, although the two eligible studies (Heinrich et al., 2011; Thomas et al., 2008) employed different standardized scales (Fahrenberg, 1975; Haugland and Wold, 2001) they used similar cut-off points (a symptom was considered to be present if occurred “nearly once every week” and “at least twice a month” respectively) and the same time reference (“during the last six months”). For the assessment of sleep problems, most of the analyzed studies used summarized items on sleep quality (Hutter et al., 2006; Mohler et al., 2010; Thomas et al., 2008).

In the study of Hutter et al. (2006) a median split was applied for the total score of sleep quality (OR and 95% CI were available after personal communication with the original authors). In the study related to Mohler et al. (2010) a number of questions about subjective sleep quality were summarized into a binary sleep quality score (ranging between 0 and 12); a score of ≤ 8 was considered as an indication of having sleep problems. The time reference for these two studies was “during the last month” and “during the last four months” respectively. The scales and cut-off points for the studies of Thomas et al. (2008) and Heinrich et al. (2011) were the same as for the measurement of “chronic” NSPS which were previously described.

There were between 919 and 1897 study participants included in each analysis. The publication dates of the studies included ranged between 2006 and 2011. The forest plots for summarizing the meta-analyses for the 7 outcomes are shown in Figs. 2 and 3. Heterogeneity was negligible to moderate for the NSPS that were measured based on their frequency (acute) and negligible to low for the NSPS that their assessment was based on their frequency (chronic). There was no publication bias apparent. Analyses did not show a significant effect of higher exposure levels on any of the examined outcomes (Table 5, Figs. 2 and 3).

Two of the analyzed studies on acute NSPS investigated symptom report in relation to exposure during both morning and afternoon hours (Heinrich et al., 2010; Thomas et al., 2008); since in the abovementioned meta-analyses we used the ORs for symptoms occurring during morning hours, additional analyses were performed replacing these ORs with the ones for symptoms reported in the afternoon. Statistically significant results were observed for headache (OR=1.9; 95% CI=1.07–3.49, p=0.03) and dizziness-related problems (OR=1.54; 95% CI=1.02–2.31, p=0.04), while the risk estimate for the rest of the acute outcomes remained non-significant (combination problems: OR=1.4; 95% CI=0.81–2.41, p=0.22, fatigue-related problems: OR=0.92; 95% CI=0.48–1.77, p=0.82). An extra sensitivity analysis was performed by integrating the OR of the studies excluded from the meta-analyses (based on the quality and comparability criteria) into the principal analyses. This was possible for 2 studies assessing headache based on its frequency (Abdel-Rassoul et al., 2006; Preece et al., 2007) and 2 assessing sleep problems (Abdel-Rassoul et al., 2006; Abelín et al., 2006); the recalculated pooled estimate remained non-significant for chronic headache (OR=2.03; 95% CI=0.79–5.19, p=0.14) and for sleep problems (OR=1.65; 95% CI=1.00–2.72, p=0.05). In line with the qualitative evaluation, there were very high levels of statistical heterogeneity (I² = 89% and I² = 70%), which demonstrate the incomparability of these studies, since the exposure characterization methods, reported symptom scales and especially the cut-off points varied considerably.

4. Discussion

The present systematic review identified the observational epidemiological studies conducted during the last eleven years on the effect of actual and perceived EMF exposure on the report of NSPS in the general population. Using sensitive search strategies and strict quality criteria, we distinguished the most examined NSPS and assessed the strength of evidence for an association with higher exposure levels. Meta-analyses were conducted to quantify the associations.

The review showed that there is no consistent association between actual exposure to EMF and occurrence of NSPS in the general population. Most of the studies suggested either no significant effect of higher exposure levels as in the case of fatigue-related symptoms and concentration difficulties, or contradictory results as in the case of dizziness-related symptoms, sleep problems and headache. It was also observed that methodological quality was an important component for the strength of the associations, since studies with a higher risk of bias, mainly regarding exposure assessment and sample selection, reported more significant associations.

More recent studies which tend to employ advanced exposure characterization methods did not suggest a significant effect; this is in agreement with the findings of Röösli and Hug (2011). Studies on perceived exposure showed generally stronger symptomatic effects and more consistent patterns, indicating an association with concentrations and headache, while most of them yielded non-significant or contradictory results for sleep problems, dizziness, fatigue-related symptoms and tinnitus. Differences in the conceptual framework of perceived exposure and variation in symptom and...
exposure assessment prevented us from conducting a meta-analysis of these studies.

Pooling the risk estimates of studies with a smaller chance of exposure misclassification and selection and confounding bias, the performed meta-analyses yielded no significant risk difference between low exposed and highly exposed individuals regarding symptom frequency and severity. In a sensitivity analysis of “acute” symptoms, when we pooled the ORs for exposure measurements “during afternoon hours” instead of exposure “during morning hours” for two of the studies, analyses yielded statistical significance only for headache and dizziness-related problems. This is probably due to the nearly significant OR in the study with the most power (Heinrich et al., 2010). Since this was the case for a number of associations in that study, the authors attributed it to multiple testing, stating that after considering exposure as a 90% cut-off in the analyses (data were not available), any significant association disappeared.

It is notable that while 9 out of 13 reviewed studies on actual exposure data suggest an association for at least one symptom, when we qualitatively examined these associations per symptom group, only the effect on headache was slightly more often significant. In this qualitative assessment we did not exclude studies of higher chance of bias which are prone to effect overestimation. In the meta-analysis, where those studies were excluded, all the associations were found to be non-significant. Since quality assessment in meta-analysis is often controversial, in an additional sensitivity analysis we pooled the risk ratio of studies with higher probability of bias in the principal analyses; the summary effect was higher but heterogeneity was striking. Despite the non-significant results, it is noteworthy that the vast majority of the exposure–symptom associations in the studies on actual exposure show a positive association. Independently of the study quality, exposure and outcome measures and examined symptoms, people who are exposed to higher levels of EMF, tend to report NSPS more frequently or severely than their “unexposed” counterpart. Possible explanations for this phenomenon could be just chance, selection bias leading to overestimation of the effect, positive-outcome bias in peer-review literature (Emerson et al., 2010), the lack of sufficient exposure contrast which could mask an exposure-outcome association if one existed, or the small prevalence in the general population of people sensitive to EMF, which could reduce the power for the detection of a significant effect. Additionally, possible exposure misclassification effects cannot be dismissed due to the existing limitations in exposure characterization (Röösli and Hug, 2011).

The strengths of this systematic review include a comprehensive search strategy, the examination of studies on both actual and

![Fig. 2. Forest plots of random-effect meta-analyses of observational studies on the association between actual EMF exposure and NSPS for 4 self-reported outcomes based on severity.](image-url)
perceived exposure and the performance of meta-analyses. Important publication bias as a result of preferential publication of studies with significant findings is unlikely to have occurred as Egger’s test on bias also indicated. However, in some cases Egger’s test could not calculate the bias risk due to the limited number of studies. Among the articles excluded due to inadequacy of the provided information and lack of minimal confounding adjustment, only one concerned actual exposure, suggesting a positive significant association with various NSPS (Eger and Jahn, 2010). All the other excluded studies focused on perceived exposure, with the vast majority reporting a significant effect, which was not adjusted for confounders (Appendix A).

This is the first time that a meta-analytic study is conducted for the effect of EMF on NSPS. The only formal meta-analysis to date in this research field focused on the individual ability to perceive short-term EMF exposure tested by randomized double-blind trials (Röösli, 2008; Röösli et al., 2010), including only a small number of studies. In the present meta-analyses, a considerable number of subjects were included, and all the analyzed studies were considered comparable in terms of study design, type of exposure source, exposure and outcome assessment. Although there was some variation in the measured exposure levels across the studies, they all were much lower than the safety limits as established by ICNIRP (1998).

Our meta-analysis has a number of limitations, such as the small number of comparable studies available for analysis, which however reflects that there are only a few comparable high quality studies addressing this issue. This prevented us from performing a meta-regression with other explanatory variables. Another shortcoming might be the fact that the study with the most statistical power was restricted to the age groups between 13 and 17 years old, which could constitute a source of heterogeneity. Nevertheless, epidemiological studies on actual exposure often set the 15 years of age or even lower as age limit for participation (Berg-Beckhoff et al., 2009; Blettner et al., 2009) and no important differences between adolescents and young adults have been shown in terms of symptom patterns, even for larger age contrasts (Yzermans and Oskam, 1990). Finally, some between-study variation was expected due to the classification of symptoms in groups and a few differences in cut-off points as was described in detail in the Results section.

This review included studies on actual as well as perceived exposure to EMF. Since people are not able to accurately self-estimate the magnitude of personal exposure to EMF sources (Frei et al., 2010; Inyang et al., 2008; Vrijheid et al., 2009), we used perceived exposure as an indicator of a nocebo phenomenon that could possibly indicate underlying psychological processes. The subjective belief of being exposed to a hazardous environmental source could reinforce the alertness for the presence of potential exposure indicators, the expectations of symptom occurrence and consequently the development and report of symptoms (Landgrebe et al., 2008). In the broader literature a number of studies have accentuated the role of psychologically-oriented factors in the report of NSPS attributed to environmental exposures (Johansson et al., 2010; Landgrebe et al., 2008; Osterberg et al., 2007; Persson et al., 2008; Rubin et al., 2006, 2008). However, most of the reviewed studies used perceived exposure as a proxy for actual exposure. This may explain the inconsistency across results. More recently published studies on actual exposure (Heinrich et al., 2010, 2011; Möhler et al., 2010) investigated the effect of perceived exposure as well, together with some psychological components such as environmental worries as confounders, but evidence regarding psychological determinants of NSPS related to EMF is still very limited and consensus about a conceptual framework on their mediating or moderating role is lacking.

Although, in terms of design, experimental studies are preferable for the clarification of causal relationships, observational studies allow the investigation of longer-term exposures and outcomes and
evaluation of possible mediating determinants in larger population samples. Exposure assessment remains a major challenge. On the one hand, methods such as self-reported exposure or geo-coded distance are not sufficient surrogates for personal exposure, and spot measurements provide only limited knowledge on exposure for specific locations (Frei et al., 2010). On the other hand, personal exposure measurements with exposimeters come with biases due to calibration issues, arrival angle dependent response, and body shielding, which lead to underestimation of the actual exposure (Bolte et al., 2011; Mann, 2010). Also, performing personal exposure measurements in large groups is very time consuming and expensive and therefore may not be feasible for large, especially cohort, studies.

Nevertheless, personal exposure measurements are recommended, as they are actually measuring one’s exposure during all activities at all locations (Neubauer et al., 2007). If it is not feasible to measure every group member, a prediction model based on modeled exposure of fixed transmitters and exposimeter measurements may be the best compromise (Frei et al., 2009, 2010).

Since the restriction of sources of bias is of vital importance, future epidemiological studies should be particularly careful regarding the sample selection and data collection; the combination of electronic medical records from general practices and self-reported health data in conjunction with exposure data, would be an important step forward in this field of research. For future research, it is also suggested that instead of adopting either the psychogenic or the bioelectromagnetic hypothesis for the explanation of NSPS in relation to EMF, the exposure–outcome association should be considered as a product of an interaction between actual exposure, the perception of the magnitude of being exposed and psychological factors, consonant to a psychological approach.

In light of this systematic review, and taking findings from systematic evaluation of experimental evidence into account (Röösli and Hug, 2011; Röösli et al., 2010; Rubin et al., 2009) it is concluded that there is no direct association between actual exposure to EMF and NSPS. An association between NSPS and perceived exposure seems to be stronger and more consistent, but striking heterogeneity regarding the conceptual framework and assessment of exposure and outcome prevents from solid conclusions. The establishment of an international protocol of harmonization of concepts and exposure–outcome characterization would minimize the methodological obstacles in epidemiological research on EMF and NSPS and strengthen the interpretations of future meta-analytic studies.

5. Conclusions

There are no indications for an association between higher levels of actual EMF exposure and frequency or severity of NSPS in the general population. An association with perceived exposure seems to exist, but evidence is still scarce mainly because of between-study differences in the conceptual framework and measurement. More epidemiological studies are needed, using comparable methods and instruments to assess exposure and outcome and investigating the role of perceived exposure and mediating psychological components in conjunction with actual exposure. Studies on long-term effects of residential EMF exposure are of particular importance in order to enhance our knowledge.

Funding source

This work was supported by The Netherlands Organisation for Health Research and Development (ZonMw). This study is part of the Dutch project EMPHASIS “Non-specific physical symptoms in relation to actual and perceived exposure to EMF and the underlying mechanisms”.

Conflict of interest statement

None declared.

Acknowledgments

The authors thank all investigators who kindly provided additional information from their studies. They would also like to thank Wim ten Have for his help with the development of the literature search strategy and search in the different databases and Dr. Rik Bogers and Dr. Anke Huss for their advice and general feedback on the paper.
